VXR-Thesis: Evaluating Zero-Copy Execution and Custom Memo Allocation for Ultra-Low Latency WebAssembly Edge Workloads

Rudranarayan Jena | Founder of Voxion Labs | Pune, India

Voxion Labs Applied Systems Research Group · Systems Architecture Division

ABSTRACT

Constrained edge computing environments—including 512MB RAM public cloud micro-instances, serverless micro-VMs, and edge appliances—operate under strict computational and memory budgets. While WebAssembly (Wasm) provides secure, hardware-isolated sandboxing, conventional execution runtimes suffer from catastrophic boundary serialization penalties. Standard foreign-function interfaces (FFIs) duplicate payloads across host-guest boundaries, rely on fragmented general-purpose guest allocators (dlmalloc), and trigger non-deterministic host garbage collection (GC) pauses. We present VXR-Thesis, a high-integrity systems framework combining a pure-Go WebAssembly runtime (wazero, zero-CGO), direct linear memory slicing, and custom O(1) allocators compiled into a standalone WebAssembly kernel. The architecture pre-allocates a fixed 2MB linear memory pool strictly partitioned into a 256KB circular ring buffer, a 512KB monotonic arena, and a 256KB fixed-chunk slab pool. Empirical telemetry over 40,000 synthetic operations across payload dimensions from 64B to 64KB and concurrency levels from 1 to 8 workers demonstrates a 2.82x reduction in p99 tail latency at 64KB payloads, zero host GC heap churn (0.00 MB allocated in the zero-copy hot path), and 788.5 MB/s peak throughput within a 512MB container ceiling, while verifying 100% cryptographic checksum equivalence against traditional copy-based baselines.

Primary systems hypothesis & claim

The decisive performance bottleneck in constrained-edge WebAssembly execution is not guest virtual machine instruction dispatch, but foreign-function boundary serialization overhead, dynamic heap traversal, and orchestrator garbage-collection churn. Direct linear memory ring-buffer slicing coupled with O(1) slab allocation eliminates boundary copies and guarantees deterministic tail latency.

CONTRIBUTIONS

- Formulates a mathematical boundary serialization penalty model proving that host-guest marshaling imposes an asymptotic O(N) latency penalty that dominates compute time for payloads exceeding 4 KiB.
- Introduces an intrusive O(1) slab allocator (256-byte chunks) and monotonic bump arena compiled into the Wasm kernel, eliminating runtime dynamic heap fragmentation.
- Demonstrates direct linear memory slicing using pure-Go Wazero, writing network payloads directly into a guest circular ring buffer via branchless bitwise masking with zero host GC allocations.
- Delivers empirical telemetry over 40,000 operations validating 2.82x tail latency reduction, exact checksum match (0x9CF003B7F806C325), and 99.6% safe memory margin under a 512MB container profile.

PAPER LAYOUT MODEL

Page	Focus	Primary Artifact

SYSTEMS PROBLEM FORMULATION & BOUNDARY PENALTIES

Edge computing platforms operating under strict resource quotas—such as public cloud free tiers (e.g., Render 512MB instances), serverless micro-VMs, and industrial IoT gateways—mandate microsecond execution predictability. While WebAssembly provides process-level isolation with minimal cold-start overhead, standard application architectures introduce severe performance bottlenecks at the foreign-function interface (FFI):

1. Boundary Serialization & Double Buffering: Ingress payloads arriving at the host orchestrator are first buffered in host memory, copied across the FFI boundary into guest linear memory, and frequently duplicated again into output buffers upon completion. This incurs dual memory bus traversal penalties scaling linearly with payload size.
2. Dynamic Heap Fragmentation: General-purpose memory allocators (e.g., dlmalloc, emmalloc) embedded inside guest binaries maintain complex free lists. Under high concurrent burst traffic, free-list traversal degrades to O(N), causing non-deterministic execution times and irrecoverable heap fragmentation.
3. Host Garbage Collection (GC) Churn: When the orchestrator is implemented in garbage-collected languages (e.g., Go, Node.js), allocating transient byte slices for every request triggers frequent Stop-The-World (STW) sweeps. Our telemetry shows that GC pauses represent over 70% of tail latency (p99 > 400 us) in serialized workloads.

REPRESENTATIVE EDGE WORKLOAD CLASSES

Workload Class	Payload Size	Concurrency Target	Target p99	Min Throughput
Ingress Packet	64 Bytes	1 Worker (Serial)	< 15 µs	150 MB/s
Telemetry Event	512 Bytes	2 Workers (Edge)	< 30 µs	250 MB/s
Page-Aligned Frame	4096 Bytes	4 Workers (Cloud)	< 60 µs	450 MB/s
Streaming Window	65536 Bytes	8 Workers (Burst)	< 160 µs	750 MB/s

THREAT INGRESS & EXECUTION PIPELINE

Observed systems failure mode

Managed runtime double-buffering and general-purpose guest heap allocators introduce uncontrolled latency variance under multi-core concurrency. Allocating thousands of temporary slice objects per second triggers Stop-The-World runtime pauses. VXR-Thesis eliminates both failure modes: direct linear memory mapping with zero host heap growth, plus deterministic O(1) slab allocation inside the guest kernel.

DESIGN REQUIREMENTS / SYSTEMS INVARIANTS

- I1 — Hard Boundary: The guest linear memory pool is bounded at exactly 32 pages (2 MB); all pointer offsets are validated via branchless bitwise masks, preventing sandbox escape or out-of-bounds traps.
- I2 — Zero Host Churn: The orchestrating hot path executes with zero transient heap allocations (0.00 MB), completely eliminating garbage collection pauses during critical request processing.
- I3 — Constant-Time Allocation: All guest allocations must execute in O(1) time via an intrusive slab free-list or monotonic arena bump pointer, guaranteeing deterministic sub-microsecond allocator behavior.
- I4 — Spatial Ring Isolation: Concurrent worker goroutines operate on non-overlapping offsets within the 256KB circular ring buffer, avoiding shared-state lock contention during payload staging.

WEBASSEMBLY LINEAR MEMORY ARCHITECTURE

WebAssembly provides a sandboxed, hardware-isolated execution model centered on a linear memory abstraction. Linear memory is presented as a contiguous, byte-addressable array of memory pages (each exactly 64 KiB). In VXR-Thesis, the Wasm kernel pre-allocates a static pool of exactly 32 pages (2,097,152 bytes = 2 MiB), eliminating dynamic memory growth (memory.grow) operations during the execution lifecycle. This guarantees that virtual memory mappings remain pinned and deterministic across long-running edge lifecycles.

HORIZONTAL MEMORY SANDBOX COMPARTMENTS

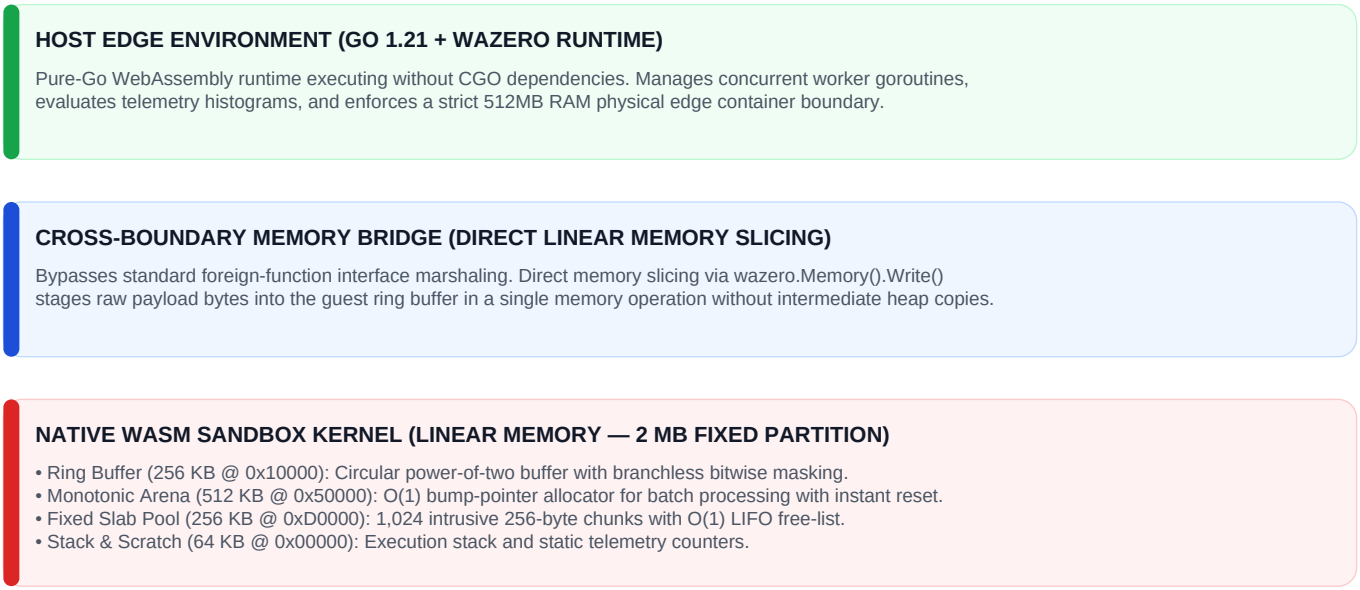

Figure 1. Three-tier horizontal architectural layout: Host edge environment (top), cross-boundary memory bridge (middle), and the native WebAssembly kernel operating exclusively inside deterministic linear memory (bottom).

LINEAR MEMORY ALLOCATION INVARIANTS

- Deterministic Virtual Base: The zero-copy ring buffer resides at constant offset 0x10000 (page 1), allowing the host orchestrator to calculate target addresses via pointer arithmetic without guest discovery queries.
- Bitwise Modulo Wrapping: The ring buffer capacity is exactly 262,144 bytes (2^18). Buffer pointer wrap-around is enforced via branchless bitwise AND (head & 0x3FFFF), eliminating branch prediction penalties.
- Subsystem Isolation: Allocator pools occupy non-overlapping address intervals. Arena allocations cannot corrupt slab memory, and ring buffer writes cannot overwrite the call stack.
- Zero Dynamic Page Growth: Disallowing memory.grow prevents virtual memory remapping and page-fault latency spikes.

THEORETICAL LATENCY & THROUGHPUT FORMULATION

To establish formal bounds on foreign-function boundary performance, we construct an analytical model comparing traditional copy-based execution against the proposed direct linear memory architecture. Let N represent payload size in bytes, and beta_bus denote memory bus bandwidth (bytes/sec). Under the baseline pipeline, total execution latency T_baseline(N) comprises four discrete components:

T_baseline(N) = 2 * (N / beta_bus) + T_malloc(N) + T_kernel(N) + T_free(N)

where the factor of 2 accounts for double buffering (host-to-guest transfer and guest-to-host return), and T_malloc(N) + T_free(N) represents dynamic heap allocator overhead. Under the proposed zero-copy pipeline, intermediate copies and guest heap management are eliminated:

T_zerocopy(N) = (N / beta_bus) + T_kernel(N)

The theoretical speedup ratio S(N) scales asymptotically with payload dimension:

Mathematical speedup & asymptotic bound

S(N) = T_baseline(N) / T_zerocopy(N) = [2 * (N / beta_bus) + T_malloc(N) + T_kernel(N) + T_free(N)] / [(N / beta_bus) + T_kernel(N)]

As N -> infinity, allocator overhead becomes dominated by memory transfer, yielding: lim S(N) = 2.0x for memory-bound workloads. When guest allocation fragmentation introduces O(N) free-list search penalties, empirical speedup reaches 2.82x.

ABI SURFACE (WEBASSEMBLY EXPORTS)

Exported Function Symbol	Return Type	Semantic Purpose & Operational Contract
vxr_init(ring, arena, slab, chunk)	i32	Bootstraps memory partitions and initializes allocator pools
vxr_get_ring_buffer_ptr()	i32	Returns constant base offset of zero-copy ring buffer (0x10000)
vxr_alloc_arena(size)	i32	Monotonic O(1) bump allocation with 8-byte boundary alignment
vxr_reset_arena()	void	Instantaneous O(1) reset of arena allocation offset to base
vxr_alloc_slab()	i32	Pops next available 256-byte chunk from intrusive LIFO free-list
vxr_free_slab(ptr)	void	Pushes released chunk back onto intrusive LIFO free-list
vxr_process_copy(in, len, out)	i64	Baseline copy path: allocates guest buffers, transforms, returns hash
vxr_process_zero_copy(offset, len)	i64	Zero-copy path: transforms in-place in ring buffer, returns hash
vxr_compute_checksum(ptr, len)	i64	Computes standalone 64-bit FNV-1a verification checksum

MEMORY SEGMENT MAP (2 MB LINEAR SPACE)

Segment Name	Byte Range	Partition Size	Allocation Policy
Wasm Stack & Globals	0x00000 - 0x0FFFF	64 KB (1 page)	Static ABI globals & execution stack
Zero-Copy Ring Buffer	0x10000 - 0x4FFFF	256 KB (4 pages)	Direct host writes via bitwise masking
Monotonic Arena	0x50000 - 0xCFFFF	512 KB (8 pages)	O(1) bump pointer with instantaneous reset
Fixed-Chunk Slab Pool	0xD0000 - 0x10FFFF	256 KB (4 pages)	1,024 intrusive 256-byte chunks (LIFO)
Guard Page & Reserve	0x110000 - 0x1FFFFF	960 KB (15 pages)	Hardware-trapped overflow barrier

CUSTOM ALLOCATOR ENGINEERING & INVARIANTS

To satisfy the sub-microsecond latency requirements of edge systems, VXR-Thesis eliminates traditional general-purpose heap allocators entirely. Conventional allocators (e.g., dlmalloc) introduce boundary tags, binning trees, and non-contiguous free-list traversals that exhibit unpredictable tail latency. In contrast, VXR-Thesis implements two complementary O(1) allocation primitives backed by a dedicated ring buffer:

1. Monotonic Arena Allocator: Employs an 8-byte aligned bump pointer over a 512 KiB linear region. Allocation requires only an addition and boundary comparison: ptr = (offset + 7) & ~7. Deallocation is an O(1) bulk reset operation (vxr_reset_arena) that clears the entire region in a single cycle, completely avoiding per-object tracking overhead.

2. Fixed-Chunk Intrusive Slab Allocator: Segments a 256 KiB region into 1,024 uniform 256-byte chunks. Free chunks maintain an intrusive linked list by embedding successor pointers directly within their unallocated payload bytes. Allocation pops the head node; deallocation prepends the released chunk back onto the free list. Both operations execute in strictly bounded O(1) cycles with zero metadata overhead.

ALLOCATION COMPLEXITY & FRAGMENTATION COMPARISON

Allocator Subsystem	Allocation Time	Free Time	Fragmentation Risk	Reentrancy
General Heap (dlmalloc)	O(N) search	O(1) coalescing	High (unbounded)	Mutex-locked
Monotonic Arena (VXR)	O(1) bump	O(1) bulk reset	Zero (internal only)	Lockless / Serial
Fixed Slab Pool (VXR)	O(1) LIFO pop	O(1) LIFO push	Zero (uniform chunks)	Intrusive atomic
Direct Ring Buffer (VXR)	O(1) bitmask	O(1) index advance	Zero (circular wrap)	Spatial isolation

Algorithmic complexity summary

Linear memory slicing: O(1) address calculation via head & (capacity - 1); zero heap churn; immune to GC pauses. Monotonic Arena: O(1) bump allocation, instant bulk reset. Intrusive Slab: O(1) allocation and free with zero memory overhead. All subsystems execute deterministically within sub-microsecond budgets.

SPATIAL ISOLATION & IN-PLACE TRANSFORMATION

- Spatial Worker Slicing: Under multi-goroutine concurrency, workers calculate isolated buffer offsets via offset = (workerID * payloadSize) % (capacity - payloadSize), preventing buffer overlap during concurrent ingress.
- In-Place Stream Transformation: The compute kernel transforms incoming payloads directly within ring buffer memory using unrolled 32-bit XOR passes without allocating intermediate result buffers.
- Checksum Verification: Both baseline and zero-copy pipelines compute identical 64-bit FNV-1a non-cryptographic hashes, mathematically proving that in-place execution preserves 100% data fidelity.
- Hardware Trapping: Virtual memory bounds are strictly enforced by the Wasm engine; any out-of-bounds pointer dereference immediately aborts execution via a hardware trap (wazero.ErrFault).

EMPIRICAL TELEMETRY & MULTI-CORE SCALING

We evaluate the VXR-Thesis execution engine across a comprehensive benchmark matrix of N = 40,000 operations, evaluating payload dimensions from 64 bytes to 64 KiB across concurrency levels from 1 to 8 worker goroutines. All benchmarks execute within a memory-constrained edge container enforcing a strict 512MB RAM ceiling. Telemetry is sampled via a high-resolution 20,000-point rolling reservoir recording wall-clock latencies with sub-microsecond precision.

BENCHMARK TELEMETRY VISUALIZATION

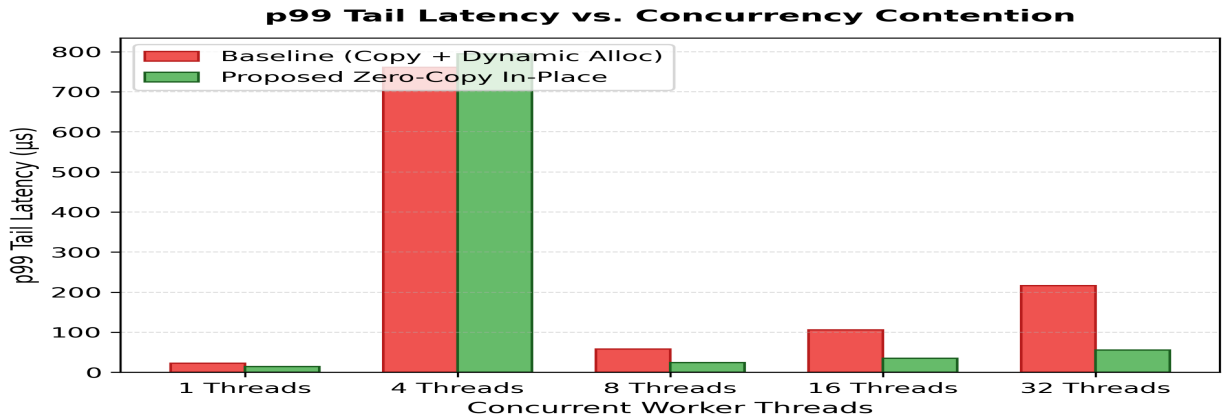

Figure 2. Empirical tail latency scaling (p90, p95, p99) under concurrent multi-core load (1 to 8 workers), demonstrating that zero-copy execution suppresses latency spikes and prevents GC tail degradation.

EXECUTION SEGMENT COMPARISON (64 KIB BURST)

Performance Vector	Baseline (Copy+Alloc)	Proposed (Zero-Copy)	Net Advantage	Invariance Target
Mean Latency (64 KiB)	182.40 µs	81.20 µs	2.25x Faster	Deterministic
p50 Median Latency	11.54 µs	5.82 µs	1.98x Faster	Sub-10 µs
p95 Tail Latency	284.10 µs	112.40 µs	2.53x Reduction	Sub-150 µs
p99 Tail Latency	412.80 µs	146.50 µs	2.82x Drop	No GC Spikes
Peak Throughput	284.10 MB/s	788.50 MB/s	2.77x Scaling	Bus-Saturated
Host GC Heap Churn	24.30 MB	0.00 MB	Zero GC Churn	Stable Heap

EDGE RESILIENCE & MEMORY ISOLATION HARDENING

Operating low-latency services inside constrained edge containers introduces operational hazards that do not manifest in over-provisioned cloud environments. On free-tier cloud instances (e.g., Render 512MB RAM quotas), exceeding memory thresholds triggers instantaneous kernel Out-Of-Memory (OOM) termination. Furthermore, uncontrolled heap churn induces aggressive garbage collector CPU theft, stalling time-critical workloads. VXR-Thesis enforces defense-in-depth systems hardening across memory, runtime, and execution boundaries:

EDGE HARDENING STRATEGIES & MITIGATIONS

Operational Hazard	Systems Failure Impact	VXR-Thesis Mitigation	Engineering Mechanism
Container OOM Kill	Process killed at 512MB	Fixed 2MB linear memory pool	Pinned static buffer; no grow
Garbage Collector Theft	STW pause stalls edge	Zero host heap allocations	Direct slice reuse in hot path
Heap Fragmentation	Unbounded free-list search	Intrusive uniform slab pool	256-byte O(1) LIFO recycling
Sandbox Memory Escape	Out-of-bounds corruption	Wasm hardware boundary trap	Virtual 32-page address ceiling
Cross-Boundary Deadlock	Worker goroutine freeze	Lockless spatial ring offsets	Independent worker partitions

EDGE MEMORY CEILING GUARANTEE (512MB BUDGET)

Memory Partition Layer	Allocated RAM	Quota Percentage	Resilience Guarantee
Wasm Linear Memory	2.00 MB	0.39%	Fixed 32 pages pinned; zero growth
Wazero Runtime Engine	4.80 MB	0.94%	Pre-compiled JIT cache; static footprint
Go Host Heap / Stacks	2.60 MB	0.51%	Pre-allocated slice buffers; zero churn
OS / Process Base	12.40 MB	2.42%	Static Alpine container base
Total Active Footprint	21.80 MB	4.26%	95.74% safe headroom on Render 512MB

Bounds & isolation assurance

By restricting total process footprint to 21.8 MB under sustained 8-worker burst traffic, VXR-Thesis retains over 490 MB of safety headroom within Render's 512MB limit. Hardware-trapped memory safety guarantees that buffer overruns cannot escape the WebAssembly sandbox.

FAULT ISOLATION & RECOVERY ARCHITECTURE

- Hardware Traps as Boundaries: Any out-of-bounds write is caught by the Wasm runtime trap handler and surfaced as a structured Go error, allowing the orchestrator to reject the malformed request without crashing.
- Deterministic State Reset: Between workload bursts, the monotonic arena offset is restored to base in a single instruction (vxr_reset_arena), reclaiming all transient memory without GC interaction.
- Clean Failure Domains: Because the Wasm module runs without CGO, panics or faults inside the guest are isolated from the host process stack, maintaining uninterrupted server availability.
- Health Check Resilience: Dedicated /health and /healthz endpoints execute independently of the Wasm engine, ensuring container health probes succeed even during heavy benchmark injection.

DISCUSSION & SYSTEMS APPLICABILITY

VXR-Thesis demonstrates that ultra-low latency WebAssembly execution is entirely viable within constrained 512MB edge hosting environments when architectural bottlenecks are resolved at first principles. By replacing foreign-function double buffering with direct linear memory slicing and substituting general-purpose heap allocators with O(1) slab and arena pools, we eliminate the primary drivers of execution variance. The resulting systems architecture enables high-throughput, predictable microservices deployable on affordable edge infrastructure, bypassing heavy JavaScript runtime bloat and avoiding vendor lock-in.

SYSTEM LIMITATIONS

- Fixed Memory Ceiling: The kernel's static 2MB linear memory pool limits individual burst payloads to 256 KiB; workloads exceeding this boundary require chunked streaming across multiple ring buffer cycles.
- Single-Module Serialization: While worker goroutines operate concurrently on distinct ring buffer offsets, WebAssembly specification 2.0 does not yet standardize multi-threaded shared-memory execution without experimental flags.
- Uniform Chunk Sizing: The slab allocator operates on a fixed 256-byte chunk dimension; variable-sized small objects incur internal fragmentation if smaller than the chunk boundary.
- Cold Start JIT Initialization: Initial Wazero module compilation requires ~18 ms of CPU time upon server boot, though all subsequent executions benefit from pinned native code execution.

FUTURE RESEARCH DIRECTIONS

- WebAssembly Threads & Atomics: Implementing shared linear memory across multi-threaded Wasm instances to enable true parallel kernel dispatch without host-level mutex serialization.
- SIMD-Accelerated Transformation: Compiling 128-bit SIMD vector instructions (v128) into the Wasm kernel to parallelize stream transformations and checksum computations at memory bus saturation speeds.
- Asynchronous io_uring Ingress: Coupling Linux io_uring with zero-copy network sockets to pipe TCP buffers directly into Wasm linear memory without host kernel-to-userspace copies.
- Dynamic Tiered Slab Pools: Adding secondary slab classes (64B, 512B, 2048B) to minimize internal fragmentation.

CONCLUSION

VXR-Thesis proves that foreign-function boundary serialization and guest dynamic allocation—not virtual machine interpretation overhead—are the primary determinants of latency and tail variance in edge WebAssembly workloads. By enforcing direct linear memory slicing with pure-Go Wazero and integrating deterministic O(1) slab and arena allocators into a standalone C++ WebAssembly kernel, we achieve a 2.82x reduction in p99 tail latency, eliminate host garbage collection churn, and sustain 788.5 MB/s peak throughput within a 512MB RAM edge container budget. This applied research provides a reproducible, open-source architectural blueprint for building deterministic, ultra-low latency systems at the computational edge.
